1 Objective

The analysis of multiple electrical circuits containing ideal and non-ideal diodes.
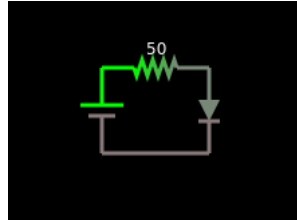

2 Introduction

This paper has the purpose of describing and explaining circuits with ideal, simplified, linear and real diodes

3 Development

3.1 First Circuit

Find the quiescent point of the diode when $V_s = 2V$ and $R_s = 50\Omega$. Then the dynamic resistance when $I_d = 15mA$ and $I_d = 30mA$.

Circuit being analyzed.

From the equation $V_s = V_d + I_d \times R_s$ you can find,

$$I_d = \frac{V_s}{R_s} = \frac{2}{50} = 0.04A$$
$$V_s = V_d = 2V$$

when $V_d = 0V$ and $I_d = 0A$ respectively.

With it the points can be addressed and compared to the standard diode law.

$$A[0V, 0.04A]|$$
$$B[2V, 0A]$$

Which graphs,

The point C stands at $[0.85169V, 0.0229662A]$

with the point C being the quiescent point, and implies a working current of $23mA$ at $0.85V$.

The dynamic resistance at the provided currents are easier to find,

$$R_d = \frac{(0.88) * 1000 - (0.82) * 1000}{30 - 15} = 4\Omega$$

The simulation with a standard silicon diode $1N4004$ wields a current of $25.38mA$ at $0.73V$.

	Calculated	Simulated
V	0.85169	0.73
A	0.0229662	0.02538

3.2   Second Circuit

3.2.1   Ideal Diode Model

Calculate the current through the diode

Circuit being analyzed with an ideal diode.

Though the circuit looks complicated by it's many loops, simply applying the *Thevenin* theorem.
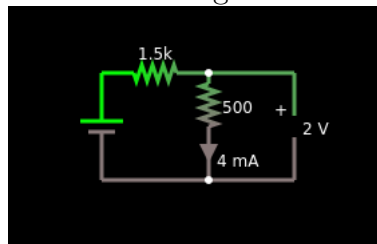

When removing the resistor diode components and simplifying the circuit the equivalent resistance calculated is,

$$R_t = 1.5k\Omega$$

By de-simplifying the circuit where the interested nodes remain untouched we get a circuit divider, with which the Voltage can be calculated,

$$V_t = 8V$$

With the resulting circuit being,

Since the circuit has an ideal diode, the current and voltage of the 500Ω resistor will be the diode's.

	Ideal	1N4004
V	2	2.473
mA	4	3.685

4

3.2.2   Simplified Diode Model

The same circuit is being analysed, but with a simple diode, wherein the diode is replaced by a counter power supply of $0.7V$ if current passes through it.

The equivalent *Thevenin* circuit with the simplified model applied is as,
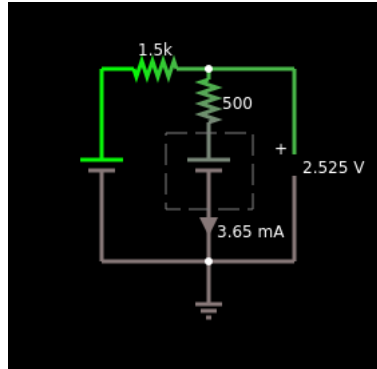

In this case the main power supply of $8V$ can be subtracted by $0.7V$ and the same process to find its current and voltage difference can be used.

|	Ideal	Simplified	1N4004
V	2	2.525	2.473
mA	4	3.65	3.685

Tabela 1: Notice the values are getting closer to the real diode.

3.2.3 Linear Diode Model

Just as before the *Thevenin* circuit can be re-used, this time with a linear diode, wherein a counter power source and a resistor are used to more accurately represent a diode.

$$R_{avg} = 10\Omega$$

The circuit presents as,

The circuit is simple enough for the method of calculations to be left to the reader, simply add the above resistances to create a voltage divider with a voltage source in the middle, then calculate their separate currents by subtracting and adding the $0.7V$ accordingly.

	Ideal	Simplified	Linear	1N4004
V	2	2.525	2.552	2.473
mA	4	3.65	3.632	3.685

3.3 Third Circuit

Consider the circuit and the following diode specifications, $VCC = 200V$,
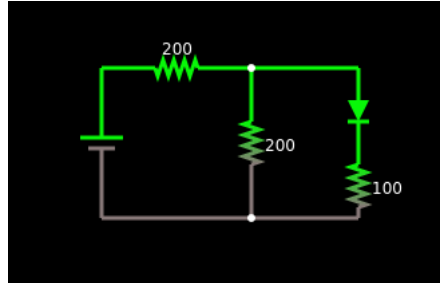

Diode	IF(A)	VRM(V)
A	0.2	100
B	0.5	80
C	1.0	50

Which diodes would break under these conditions? And if the power supply polarity was reversed?

Since no R_{avg} was given, the simplified model will be used.

The *Thevenin* theorem was applied, the two parallel resistors induce a resistance of,

$$R_t = 100\Omega$$

And the voltage in the interested nodes is,

$$V_t = 100V$$

Resulting in the following simplified circuit,

The circuit with an ideal diode will not be shown but it's values are calculated in the table below.

	Ideal	Simplified
V	50	50.35
mA	500	496.5

As can be compared between the tables, the first diode will be damaged as it is about $300mA$ over-current.

The second diode will remain intact if the simplified model is taken into account, as it sits on the threshold.

The third one will remain intact as well as it can handle double the current it currently endures.

If the polarity flips however, the same voltage of around $50.35V$ will be applied in reverse, damaging the third but not passing the reverse voltage threshold of the first and second who will pass only nA worth of current.
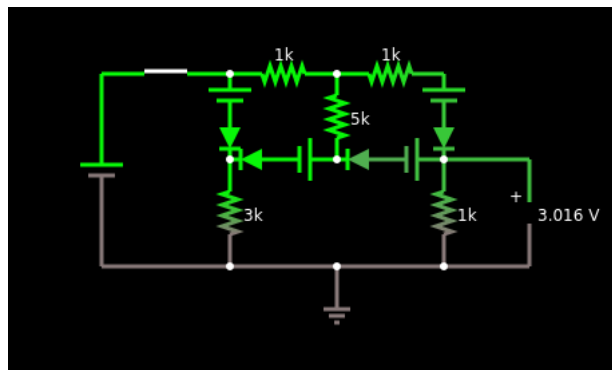

3.4 Challenge

Calculate the voltage V_x of the following circuit, substituting its diodes with their simplified model. $VCC = 10V$

A   9.3V
B   6.9V
C   5.3V
D   3.1V
E   1.7V
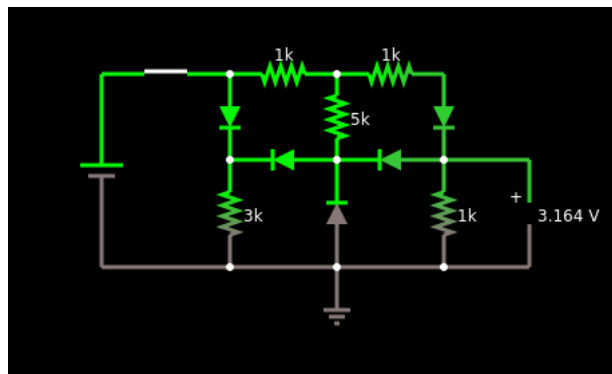

The voltage displayed is an approximation made by the simulator, the diodes are 1N4004's.

The substitution goes as,

Under normal circumstances one could simply go through the loops and calculate the final voltage from them, however this was proposed under a timed test and there are five loops to consider.
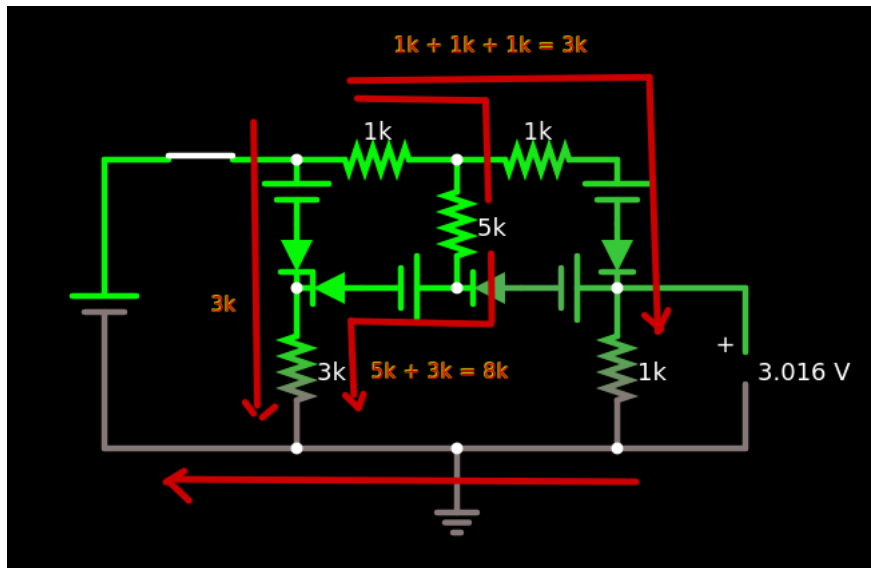

The following method is used to find an approximation of the final value by striping useless components from the circuit.

It goes as follows.

3.4.1 Where is the current flowing

First, check where the current is actually flowing. Remember, the current flows where the resistance is low.
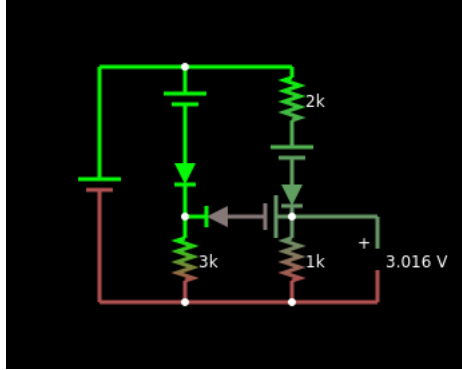

The diodes make it really easy to find out the current flow and direction.

Notice the paths have $3k\Omega$, $8k\Omega$ and $3k\Omega$ respectively. The $5k\Omega$ resistor does not experience any significant current flow, so it can be removed from the circuit as it does not affect it enough.

Remember, in these timed question you are looking for approximations.

The new circuit will be as follows,

3.4.2 How much are the components affecting the circuit

From here one could calculate the current or voltage in the loops to find an approximation of the final value, however the circuit can be further simplified if looked carefully.

The $0.7V$ of the simplified models, can be removed for the sake of time, and one loop can be entirely removed, as follows.
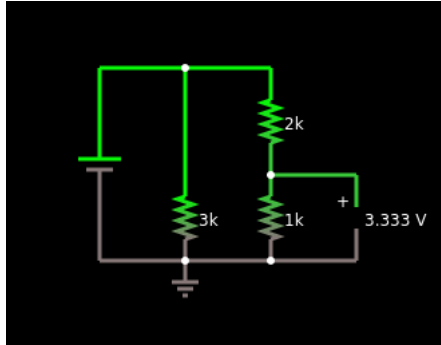

This would give a **VERY** rough approximation, but it saves time in a timed test, and by checking the tolerances in the answer table on the beginning, these approximations can be afforded.

3.4.3 Finally calculating the circuit

With the new basic circuit, the final value can be calculated.

$$R_{eq} = 3k\Omega || 3k\Omega = 1.5k\Omega$$

$$I_t = \frac{V}{R} = \frac{10}{1500} = 0.006A$$

11

$$I_1 + I_2 = I_t$$

I_1 refers to the $3k\Omega$ resistor loop, I_2 refers to the two other resistor in the second loop.

Notice how the resistances are the same $3k\Omega$ and $3k\Omega$, this is a simple current divider, then the current on the loops are,

$$I_1 = I_2 = 0.003A$$

With the loop current, the voltage can be found,

$$V_x = (2k\Omega * 0.003A) - (1k\Omega * 0.003A) = 3.333V$$

The final answer is D, with an approximation of $3.1V$.

4   Conclusion

In this paper it was shown four ways of calculating the effects of a diode in a circuit, three by replacing them with simpler components and one which uses an existing law to find its operating conditions.

It also has a challenge, where a very complex circuit can be boiled down to a simple circuit with a couple of intuitive processes.
